Re: Recent and Ongoing Formaldehyde Science Relevant to Non-Linear Dose Response Modeling

Dear Dr. Orme-Zavaleta:

EPA's Integrated Risk Information System (IRIS) program has been working to revise the 2010 draft formaldehyde IRIS assessment in response to numerous substantive recommendations made by the National Academy of Sciences (NAS) in 2011. [1] Concurrently, the American Chemistry Council's Formaldehyde Panel (the Panel) has supported scientific studies and evaluations of formaldehyde that are directly responsive to key recommendations made by the NAS.

In light of your recent appointment as the Deputy Assistant Administrator for Science in the Office of Research and Development, we write to call your attention to seminal research led by Dr. James Swenberg at the University of North Carolina. Dr. Swenberg's work specifically addresses the NAS recommendation to improve the understanding of when exogenous formaldehyde exposure can alter normal endogenous formaldehyde concentrations. His research findings reconcile the divergent statements made in the published literature, and noted by the NAS, as to whether rat nasal tumors form via a threshold mode of action (MOA) and whether inhaled formaldehyde can be systemically delivered.

Dr. Swenberg's research employs an innovative ultra-sensitive analytical method that can differentiate and measure endogenous versus exogenous formaldehyde DNA adducts or protein crosslinks in tissues throughout the body. This method has been applied in studies conducted in multiple laboratory species, and has been critical in illustrating that the metabolism of inhaled formaldehyde is rapid at the portal of entry so it does not move beyond the portal of entry or reach distal sites in the body including the bone marrow and circulating blood cells.

Dr. Swenberg's recent formaldehyde related publications include:

Committee to Review EPA's Draft IRIS Assessment of Formaldehyde. Board of Environmental Studies and Toxicology. Division of Earth and Life Sciences.

- Edrissi et al. 2017[2] demonstrated formation of exogenous adducts in the nasal epithelium and, to some extent, in trachea of rats, but not in distant tissues of lung, bo ne marrow, or white blood cells following inhalation of concentrations of 2 ppm formaldehyde for up to 28 days.
- Lai et al. 2016 [3] found exogenous formaldehyde induced DNA protein crosslinks only in the nasal tissue of rats and monkeys, but not in tissues distant to the site of initial contact.
- Yu et al. 2015[4] measured exogenous and endogenous DNA adducts in rats and monkeys and found that exogenous adducts accumulated in the rat nasal epithelium to reach steady state concentrations, with no exogenous adducts measured at tissues distant to the site of initial contact following exposure to concentrations of 15 ppm for up to 4 days. Moreover, the amounts of exogenous formaldehyde-induced adducts were 3- to 8-fold and 5- to 11-fold lower than the average amounts of endogenous formaldehyde-induced adducts in rat and monkey nasal respiratory epithelium, respectively.
- Edrissi et al . 2013[5] found that exogenous N6 -formyllysine was detected in the nasal epithelium, but was not detected in the lung, liver, or bone marrow following inhalation of concentrations up to 9.1 ppm for 6 hours.
- Lu et al . 2012[6] demonstrated that N(2) -hydroxymethyl-dG is the primary DNA adduct formed in cells following formaldehyde exposure to cells in culture. In addition, the study showed that alkylating agents induce methyl adducts at N(2) -dG and N(6) -dA positions, which are identical to the reduced forms of hydroxymethyl adducts arising from exogenous formaldehyde.
- Moeller et al . 2011[7] found that both exogenous and endogenous adducts were readily detected and quantified in the nasal tissues of groups of monkeys exposed by inhalation to 1.9 or 6.1 ppm formaldehyde for two consecutive days , with an exposure dependent increase in exogenous adducts observed. In contrast, only endogenous adduct s were detectable in the bone marrow, even though ~10 times more DNA was analyzed for this tissue than for nasal tissues . These data clearly show the formation of exogenous formaldehyde adducts in nasal DNA of primates and the lack of formation of exogenou s DNA adducts in the bone marrow.

---

These results consistently demonstrate that formaldehyde is not systemically delivered. In addition to this research, other agencies have also sought to evaluate the potential impacts of exogenous exposures. A 2014 European Food Safety Authority (EFSA) scientific report[8] evaluated endogenous formaldehyde turnover and background levels from food sources. EFSA (2014) cited literature demonstrating steady state formaldehyde concentrations in blood of 2.6 mg/L and daily endogenous turnover of 878 -1310 mg formaldehyde/kg bw/day. The EFSA evaluation found that the relative contribution of exogenous formaldehyde compared to that which is systemically produced as part of normal metabolism was negligible and illustrates the utility of conducting reality check calculations to determine if exogenous formaldehyde exposures present an appreciable risk.

To further add to the weight of the scientific evidence, the Panel is currently supporting, Dr. Swenberg's research to identify threshold levels above which exogenous formaldehyde exposure alters normal endogenous formaldehyde concentrations. Specifically, this research includes a 28 day *in vivo* (nose only) inhalation study where rats were exposed to radio-labeled formaldehyde at 0, 1, 30 or 300 ppb. Following exposures, tissue samples were collected from the nasal and upper respiratory tract, lung, bone marrow, liver, cerebrum, hippocampus, olfactory bulb, blood and plasma, for analysis. The in-life portion of the study is complete and sample analysis is underway, with results expected by the end of January 2018.

Previous scientific research has supported a threshold for formaldehyde effects and has called into question EPA's use of a linear dose-response model for the estimation of an Inhalation Unit Risk (IUR) for formaldehyde. In the 2010 draft formaldehyde IRIS assessment, EPA utilized a linear dose-response model to develop an IUR. According to the EPA's 2005 Guidelines for Carcinogen Risk Assessment,[9] the linear approach is used when there is an absence of sufficient information on MOAs for carcinogenicity or the MOA information indicates that the dose-response curve at low doses is expected to be linear. However, where alternative approaches have significant biological support, and no scientific consensus favors a single approach, an assessment may present results using alternative approaches. In the case of formaldehyde, significant mechanistic data informs the formaldehyde MOA and provides evidence of an exposure threshold in the dose-response curve for carcinogenicity. The available toxicity literature provides considerable additional evidence in animals of observed thresholds for effects from formaldehyde exposure (Woutersen et al. 1989[10]; Casanova-Schmitz et al. 1984[11]; Heck et al. 1990[12]; Swenberg et al. 2013[13]; and Starr and Swenberg 2016[14]). The work currently being

conducted by Dr. Swenberg will further add to the weight of evidence regarding effect thresholds for formaldehyde exposure. We consider the magnitude and quality of Dr. Swenberg's work to be truly "game chang ing" and critical to the fuller understanding of the effects of chronic formaldehyde exposure.

The Panel has endeavored to keep staff in the IRIS program informed of relevant new scientific data as it becomes available and we will continue to do so moving forward . Panel representatives would like to meet with you in January 2018 to discuss this important science on formaldehyde and how the results support use of a non -linear approach for formaldehyde dose - response modeling. I will contact your office next week to arrange a mutually convenient time.

Sincerely,

Kimberly Wise White, PhD
